Abstract

Ligamentum flavum hematoma (LFH) is an extremely rare compressive epidural lesion of the spine. The clinical manifestations of LFH are similar to that caused by other more common pathologies of nerve root compression like disc herniation. In the diagnosis, magnetic resonance imaging (MRI) is very important but challenging due to the changing intensities of the hematoma in relation to the stages of the aging blood. Herein, we report a case of LFH compressing the spinal canal in a 60-year-old man with pars interarticularis defect. He presented with low back pain radiating to the left leg. The neurological examination was consistent with left S1 nerve root compression. The MRI revealed a left posterior epidural mass compressing the thecal sac and S1 nerve root at the left L5–S1 level near the pars interarticularis defect. After surgical removal of the lesion, histopathological examination confirmed the diagnosis of LFH. Following surgery, he recovered rapidly. LFH due to spinal instability is important in terms of the understanding of the pathophysiological mechanisms related with LFH.

► spinal instability

Introduction

Ligamentum flavum (LF) is the longest ligamentous structure in the human body. Its main function is maintaining the upright position. Different pathological changes can occur in LF including hypertrophy, calcification/ossification, and cyst formation. In addition, rarely hematoma may occur in the LF and it is an extremely rare cause of nerve root and spinal cord compression. The first case of LF hematoma (LFH) in the literature was reported by Sweasey et al in 1992. Although LF is extended from the C2 vertebra to the sacrum, the majority of reported cases of LFH are located at the mobile segments of spine, most frequently at lumbar region. The cervical and lumbar spine receives transmitted pressure to the epidural space due to their spinal mobility. Therefore, most intraligamentous hemorrhages are observed in the mobile cervical and lumbar regions. In the literature, the reported cases are older aged, most frequently older than 60 years old, and most patients are males. The etiology and pathogenesis of LFH are not clearly defined. Thus, further studies and additional case reports will contribute to the present data. We report a case of LFH that occurred in association with spinal instability in a patient whose complaints were resolved rapidly following L5/S1 decompression surgery.

Case Presentation

A 60-year old man presented with a 3-week history of worsening low back pain radiating to the left leg. He had no recent history of trauma or lumbar surgery. His complaints were worsening during walking at approximately 50 m. Neurological examination revealed left posterolateral leg pain on stretching and hypesthesia on the left S1 dermatomes. In addition, straight leg raising test was positive on the left side.
His left Achilles reflex was hypoactive and there was also loss of left dorsiflexor muscle strength (3–4/5). Laboratory tests were unremarkable. Magnetic resonance imaging (MRI) without contrast was performed and revealed a left posterior epidural mass compressing the thecal sac at the left L5–S1 level. On the sagittal fat-suppressed T1-weighted image, there was a 1-cm hyperintense lesion that may be compatible with subacute stage hematoma (►Fig. 1A). On the T2-weighted images, the lesion was heterogeneously hypointense to spinal cord with hyperintense foci (►Fig. 1B, C). Axial T2-weighted image showed compression of the thecal sac by the lesion at L5–S1 level (►Fig. 1C). Computed tomography (CT) images revealed the pars interarticularis defect at L5–S1 level (►Fig. 2A, B). Surgical resection of the epidural lesion and transpedicular stabilization was recommended but the patient refused the application of instrumentation. Therefore, he underwent only left L5–S1 partial hemilaminectomy with excision of the epidural lesion under the aid of operation microscope. On early postoperative MRI, the lesion was seen as totally excised (►Fig. 3A, B). He recovered rapidly after surgery with resolution of neurological symptoms and low back pain. Histopathological examination of the surgical specimen revealed presence of erythrocytes in ligamentous connective tissue and confirmed the diagnosis of LFH. There was no evidence of neural tissue or malignancy (►Fig. 4). When the blood biochemistry of the patient was examined retrospectively, no pathological finding that could cause bleeding diathesis were found.

**Discussion**

The LF is composed of elastic fibers (80%) and collagen (20%) and is poorly vascularized, having only a few small vessels pass through it in young healthy people. Therefore, intraligamentous bleeding is very rare.3-5 Although the pathogenesis of the development of hematoma is still unclear, it is thought to be a degenerative process. The most commonly accepted mechanism is the bleeding of the irregular small vessels of the degenerated and hypertrophied LF.5 Significant microangiogenesis around the ruptured collagen and elastic fibers during the degenerative changes in the LF has been reported.7 Epidemiological studies have showed the evidence of a causal role of mechanical stress due to spinal instability in initiating the pathological pathway of LF hypertrophy.8,9 In our patient, LFH was associated with the degenerated LF near the pars interarticularis defect at L5–S1 level. As a precipitating factor for hematoma, the most potential suspect is minor trauma resulting from daily activities or sports. In addition, percutaneous procedures like lumbar puncture or epidural interventions and increased intra-abdominal pressure are also accused for the tearing of these vessels.10 However, it may also occur as an idiopathic form without provocation.11,12 The clinical presentation of LFH is with radiculopathy or myelopathy according to the location of pathology, similar with the other more common causes of neural compression like disc herniation. When LFH occurs in the lumbar spine, the presentation is often with low back and/or leg pain accompanied by various neurological deficits as in our patient. LFH usually occurs acutely. Chronic LFH is rarely seen and a less common cause of severe neural compression.2 In the diagnosis, MRI is the most important tool for the detection of the relationship between the lesion in the epidural space and LF.1 In most LFH cases, lesions are hyperintense on T1-weighted MRIs, while heterogeneous intensity is seen on T2-weighted images. In our case, the LFH was also hyperintense on T1-weighted fat-suppressed MRIs that may be compatible with the subacute stage of hematoma. However, the intensities of the lesion can vary in relation to the stage of the hemoglobin breakdown during the aging of the blood.6 Therefore, it is sometimes very difficult to differentiate LFH from other epidural lesions like intraspinal cystic tumors or facet cysts.13 Contrast-enhanced MRI may help in the differentiation, because enhancement is much more rare in hematoma unlike spinal tumors.14 However, in LFH, slight-to-moderate peripheral enhancements may occur.15 In addition, there are reported cases of LFH with marked enhancement which

causes preoperative suspicion that the lesion was likely to be neoplasm.\textsuperscript{16} Facet cysts are usually not enhanced, but they may also show rim enhancement.\textsuperscript{17} Consecutive MRIs may help the preoperative diagnosis by revealing signal intensity changes in relation to the stage of clothing. However, it may not be possible if the symptoms of the patient is severe. In patients who have severe pain and neurologic deficits, the standard care is surgical excision with rapid and favorable outcomes.\textsuperscript{3,18,19} In our patient, we performed decompressive microsurgical excision of the lesion due to the presence of

S1 radiculopathy. The prognosis of the patient after surgery was excellent. The diagnosis of LFH was made with the histopathological evaluation of the surgical specimen. Surgery is also recommended in some cases for the exact diagnosis. However, in stable patients, initial observation and conservative management may be warranted.

**Conclusion**

LFH is an extremely rare cause of radiculopathy and/or myelopathy. However, it should be remembered in the differential diagnosis of the epidural lesions, especially when it is seen in the lumbar region in older-aged male patients. Spinal instability that plays a role in the pathogenesis of hypertrophy and degeneration of LF is one of the cause of LFH. The patients who have severe pain and neurological deficit should be surgically managed immediately.
